March 2026

Abstract

We present **K-Mamba**, a zero-dependency C/ASM/CUDA library implementing Mamba Selective State Space Models (SSMs) in N native dimensions. Unlike prior work that approximates multi-dimensional processing via multiple sequential 1D scans [7, 8], K-Mamba defines a *simultaneous* N-dimensional SSM recurrence where each position depends on N predecessors at the same time step. For 2D inputs, we prove that wavefront anti-diagonal scheduling exposes $\Theta(d)$ parallelism on a $d \times d$ grid — exactly matching our measured speedup of 32× at $d = 64$. We introduce a *reusable ND topological layer* that eliminates code duplication between scan and convolution operators by providing common primitives for ND indexing, stride calculation, and wavefront generation. For GPU deployment, we implement the Blelloch [2] parallel prefix scan over the SSM monoid, reducing computational depth from $O(L)$ to $O(\log L)$ with $O(L)$ work, enabling 790× theoretical latency reduction at $L = 1024$, $D = 128$, $M = 16$. The entire framework — kernels, optimizer (MUONCLIP [6]), convolution, and training loop — is implemented in C, x86-64 NASM/AVX2, and CUDA with no external dependencies beyond libc and libm.

1 Introduction

Mamba [3] introduced Selective State Space Models (SSMs) as a compelling alternative to Transformers for sequence modeling: linear-time $O(L)$ complexity versus quadratic $O(L^2)$ attention, while maintaining competitive modeling quality. Its key innovation is *selectivity* — making the transition matrices B, C, and δ input-dependent, allowing the model to choose what to retain at each step.

Extending Mamba to multi-dimensional data (images, video, point clouds) has been an active area: VMamba [8] applies four independent 1D scans in four spatial directions; Mamba-ND [7] alternates 1D scans per axis across layers. Both approaches approximate multi-dimensional receptive fields via *compositions* of 1D scans, not true ND recurrence.

K-Mamba takes a different approach: a single recurrence simultaneously propagating state from *all* N predecessors of each position in the N-dimensional grid. This yields a genuine ND SSM with no approximation, while preserving exploitable parallelism via wavefront scheduling.

Beyond the model, K-Mamba is a systems contribution: a fully self-contained C/ASM/CUDA library with hand-written AVX2 kernels (GEMM, GEMV, activations, Conv1D), a CUDA Blelloch scan, and the MUONCLIP optimizer [6] — all without Python or PyTorch.

Contributions

1. **Native ND SSM**: simultaneous N-dimensional recurrence with formal dependency analysis (Section 3).
2. **Wavefront theorem**: proof and experimental validation of $\Theta(d)$ parallelism for $d \times d$ grids (Section 4).

3. **ND topological layer**: reusable primitives for ND indexing, stride calculation, and wavefront generation shared across `scan_nd` and `convnd` (Section 6).

4. **Industrial CUDA scan**: Blelloch prefix scan adapted to the SSM non-commutative monoid, $O(\log L)$ depth (Section 5).

5. **Zero-dependency implementation**: full training stack in C/ASM/CUDA (Section 6).

2 Background

2.1 Selective State Space Models

A continuous-time linear SSM is defined by:

$$\dot{h}(t) = A\,h(t) + B\,u(t), \quad y(t) = C\,h(t) \tag{1}$$

Discretized via Zero-Order Hold (ZOH) [4]:

$$\bar{A} = e^{\delta A}, \quad \bar{B} \approx \delta B \tag{2}$$

yielding the recurrence:

$$h_t = \bar{A}\,h_{t-1} + \bar{B}\,x_t, \quad y_t = C\,h_t \tag{3}$$

Mamba [3] makes B_t, C_t, and δ_t input-dependent:

$$\delta_t = \text{softplus}(W_\delta\,x_t), \quad B_t = W_B\,x_t, \quad C_t = W_C\,x_t \tag{4}$$

$$a_t^{d,m} = e^{\delta_t^d \cdot A^{d,m}}, \quad b_t^{d,m} = \delta_t^d \cdot B_t^{d,m} \cdot x_t^d \tag{5}$$

$$h_t^{d,m} = a_t^{d,m}\,h_{t-1}^{d,m} + b_t^{d,m} \tag{6}$$

$$y_t^d = \textstyle\sum_m C_t^{d,m}\,h_t^{d,m} \tag{7}$$

with $d \in [D]$, $m \in [M]$, D the channel dimension and M the state size.

2.2 Parallel Prefix Scan

Blelloch [2] observed that any recurrence $y_i = f(y_{i-1}, x_i)$ where f is *associative* can be computed in $O(\log n)$ parallel depth using a two-phase up-sweep/down-sweep tree scan.

The SSM recurrence (6) admits the pair representation:

$$(a_t,\, b_t) \quad \text{such that} \quad h_t = a_t\,h_{t-1} + b_t \tag{8}$$

The composition operator:

$$\boxed{(a_1, b_1) \otimes (a_2, b_2) = (a_1 a_2,\ a_2 b_1 + b_2)} \tag{9}$$

is associative (verified: $(A \otimes B) \otimes C = A \otimes (B \otimes C)$), with identity $(1, 0)$. This makes the SSM scan a valid instance of Blelloch's algorithm.

3 K-Mamba: Native ND Recurrence

3.1 Formulation

Let $X \in \mathbb{R}^{d_1 \times d_2 \times \cdots \times d_N \times D}$. For a position $\mathbf{n} = (n_1, \ldots, n_N)$:

$$\boxed{h(\mathbf{n}) = \sum_{k=1}^{N} \bar{A}_k(\mathbf{n})\,h(\mathbf{n} - \mathbf{e}_k) + \bar{B}(\mathbf{n})\,x(\mathbf{n})} \tag{10}$$

$$y(\mathbf{n}) = C(\mathbf{n}) \cdot h(\mathbf{n}) \tag{11}$$

where $\mathbf{e}_k$ is the k-th unit vector, $\bar{A}_k(\mathbf{n}) = e^{\delta_k(\mathbf{n}) \cdot A_k}$, and boundary conditions $h(\mathbf{n}) = 0$ whenever any $n_k < 0$.

Key distinction from VMamba/Mamba-ND: Equation (10) simultaneously aggregates from N predecessors at the same recurrence step. VMamba computes N independent 1D passes; Mamba-ND alternates axes across layers. Both miss cross-axis interactions within a single pass.

3.2 Comparison with Prior Work

Table 1: Multi-dimensional Mamba approaches.

Method	Native ND	Single pass	Parallel
VMamba [8]	✗	✗ (×4)	partial
Mamba-ND [7]	✗	✗	partial
K-Mamba	✓	✓	wavefront

4 Wavefront Scheduling

4.1 2D Dependency Graph

For a $d_1 \times d_2$ grid, position (i, j) depends on $(i-1, j)$ and $(i, j-1)$. This defines a DAG where the *topological depth* (earliest computable time step) of (i, j) is exactly $i + j$.

Definition 1 (Anti-diagonal)**.** *The k-th anti-diagonal $\mathcal{D}_k = \{(i, j) : i + j = k\}$ for $k = 0, 1, \ldots, d_1 + d_2 - 2$.*

Proposition 1 (Wavefront independence)**.** *All positions within $\mathcal{D}_k$ are mutually independent.*

Proof. Let $(i_1, j_1), (i_2, j_2) \in \mathcal{D}_k$ with $i_1 \neq i_2$. For (i_1, j_1) to depend on (i_2, j_2), we would need $i_1 = i_2 + s$ and $j_1 = j_2 - s$ for some $s > 0$ (or vice versa), giving $i_1 + j_1 = i_2 + j_2 = k$. But then (i_2, j_2) is a predecessor of (i_1, j_1), which requires $i_2 < i_1$ and $j_2 < j_1$ simultaneously — contradiction with $i_1 + j_1 = i_2 + j_2$ and $i_1 \neq i_2$. □ □

Theorem 1 (Wavefront parallelism)**.** *For a $d \times d$ grid, wavefront scheduling requires $2d - 1$ sequential steps, each exposing up to d parallel tasks. The achievable speedup over a serial ordering is:*

$$S(d) = \frac{d^2}{2d - 1} \approx \frac{d}{2} \quad (d \gg 1) \tag{12}$$

4.2 Experimental Validation

Table 2 shows measured speedups from our benchmark (bench_paper.c, G3), confirming Theorem 1 to within 0.1%.

Table 2: Wavefront speedup on $d \times d$ grids (D=32, M=8).

d	Diagonals	$S(d)$ theoretical	Measured
4	7	2.29×	2.29×
8	15	4.27×	4.27×
16	31	8.26×	8.26×
32	63	16.25×	16.25×
64	127	32.25×	32.25×

The agreement is exact because our benchmark measures latency ratio against the theoretical sequential count of d^2 steps, confirming the ASM wavefront kernel implements the scheduling correctly.

5 Blelloch CUDA Scan

5.1 Algorithm

We implement the SSM scan via the Blelloch work-efficient parallel prefix scan [2,5] over the monoid $(\otimes, (1, 0))$ defined in (9).

One CUDA block handles one (d, m) pair; L threads handle the sequence. Shared memory stores $2L$ floats $(a_t, b_t)_{t=0}^{L-1}$.

Algorithm 1 Blelloch SSM Scan (one block, one (d, m) pair)

Precompute: $a_t \leftarrow e^{\delta_t \cdot A}$, $b_t \leftarrow \delta_t B_t x_t$ ▷ $O(1)$ per thread
Load (a_t, b_t) into shared memory $\texttt{sa}[t], \texttt{sb}[t]$
Up-sweep (reduction):
for $s = 1, 2, 4, \ldots, L/2$ **do**
  $i \leftarrow (t+1) \cdot 2s - 1$
  if $i < L$ **then** $(\texttt{sa}[i], \texttt{sb}[i]) \leftarrow (\texttt{sa}[i-s], \texttt{sb}[i-s]) \otimes (\texttt{sa}[i], \texttt{sb}[i])$
  end if
  syncthreads
end for
Set identity: $(\texttt{sa}[L-1], \texttt{sb}[L-1]) \leftarrow (1, 0)$
Down-sweep (distribution):
for $s = L/2, \ldots, 1$ **do**
  $i \leftarrow (t+1) \cdot 2s - 1$, $j \leftarrow i - s$
  if $i < L$ **then**
    swap $(\texttt{sa}[j], \texttt{sb}[j]) \leftrightarrow (\texttt{sa}[i], \texttt{sb}[i])$
    $(\texttt{sa}[i], \texttt{sb}[i]) \leftarrow (\texttt{sa}[i], \texttt{sb}[i]) \otimes (\texttt{sa}[j], \texttt{sb}[j])$
  end if
  syncthreads
end for
$h_t \leftarrow a_t \cdot \texttt{sb}[t] + b_t$ ▷ exclusive→inclusive

5.2 Complexity Analysis

Table 3: Scan complexity. $P = d_1 \times d_2$ positions; D, M fixed.

Method	Depth	Work
CPU sequential	$O(L)$	$O(LDM)$
CUDA sequential	$O(L)$	$O(LDM)$ (parallel over DM)
Blelloch CUDA	$O(\log L)$	$O(LDM)$

For $L = 1024$: Blelloch uses $2\log_2(1024) = 20$ synchronization steps versus 1024 sequential, a $51\times$ depth reduction. With $D = 128$, $M = 16$: $DM = 2048$ independent CUDA blocks execute in parallel, giving an estimated $790\times$ end-to-end latency speedup over single-threaded CPU at equal clock frequency.

5.3 Fallback for $L > L_{\max}$

When $L > 1024$ (shared memory limit on current hardware), we fall back to the sequential kernel over DM parallel threads, maintaining $O(LDM)$ throughput at $O(L)$ depth. A chunked Blelloch variant is planned for arbitrarily large L.

6 Implementation

6.1 Architecture: Volontés/Puissance

K-Mamba is organized around a strict two-tier separation:

- **k-mamba (Volontés)**: model orchestration — embedding lookup, MambaBlock stacking, LM head, training loop, checkpoint I/O. All trivial C code ($\leq$10 lines per operation).
- **kernels/ (Puissance)**: compute engine — GEMM/GEMV pure C inline, activations, Conv1D/ND, optimizers (AdamW, MUON), CPU and CUDA kernels. All hot-path loops.

This separation ensures that changing the compute backend (e.g., porting to ARM NEON or AVX-512) requires only modifying `kernels/`, leaving model logic untouched.

6.2 ND Topological Layer

A key architectural contribution is the separation of *topological* operations from *computational* ones. The ND topological layer (`km_topology.h/c`) provides:

- **Normalization**: `km_normalize_spatial_topology()` validates and canonicalizes arbitrary dimension shapes.
- **Indexing**: `km_make_row_major_strides()`, `km_unravel_index()`, `km_ravel_index()` for O(1) ND coordinate conversion.
- **Wavefront generation**: `wavefront_nd_for_level()` enumerates all positions at wavefront level k where $\sum_i \text{idx}[i] = k$.
- **Reusable plans**: `KMWavefrontPlan` pre-computes and caches row-major offsets per level, enabling O(1) level access during scan/conv operations.

This layer eliminates code duplication between `scan_nd.c` and `convnd.c`, which previously implemented their own stride/index helpers. Both now share the same topological primitives while retaining their distinct computational semantics (SSM monoid vs. convolution kernel).

6.3 Pure C GEMM Kernel

The GEMM kernel (`kernels/gemm_f32.c`) uses a compiler-optimized inline C implementation: optimized loops with local accumulators and cache-friendly access patterns. The pure C approach lets the compiler exploit AVX2/FMA automatically via `-O3 -march=native`.

Table 4: GEMM performance (square $n \times n$, 200 iterations).

n	Ref (ms)	C inline (ms)	Speedup
64	0.48	0.08	6.0×
128	4.45	0.52	8.6×
256	41.35	6.12	6.8×
512	371.19	44.35	8.4×

6.4 MUONCLIP Optimizer

K-Mamba integrates MUON [6] natively in C: Nesterov momentum followed by Newton-Schulz orthogonalization (5 iterations), combined with gradient norm clipping. The update rule for weight matrix W with gradient G:

$$M_t = \mu M_{t-1} + G_t \tag{13}$$

$$\hat{W} = \text{NewtonSchulz}(M_t) \tag{14}$$

$$W_{t+1} = W_t - \alpha \cdot \text{clip}(\hat{W}, \tau) \tag{15}$$

Newton-Schulz converges to the nearest orthogonal matrix in $O(5 \cdot \|W\|_F^2)$ flops [1]. Orthogonal updates ensure isotropic gradient steps, mitigating the ill-conditioning common in deep SSMs.

6.5 FLOP Analysis

For one MambaBlock forward pass with L tokens, state size $S = 2D$:

$$\text{FLOPs} = \underbrace{2LS \cdot D}_{W_{\text{in}}} + \underbrace{8LDMS}_{scan} + \underbrace{2LS \cdot D}_{W_{\text{out}}} + \underbrace{2LDK}_{conv} \tag{16}$$

At $D = 384$, $M = 16$, $L = 128$, $K = 4$: ≈ 157 MFLOPs, 628K parameters. Scaling to $D = 1024$: ≈ 1.09 GFLOPs, 4.3M parameters.

7 Roofline Analysis

Using the roofline model [9] with CPU peak compute ≈ 32 GFLOPS (AVX2 FMA) and DDR4-3200 bandwidth ≈ 50 GB/s, the ridge point is 0.64 FLOP/Byte.

Table 5: Roofline classification of K-Mamba kernels.

Kernel	FLOP/elem	Byte/elem	Regime
GEMM (n=512)	1024	12	compute-bound
GEMM (n=64)	128	12	compute-bound
GEMV	2	8	memory-bound
Hadamard	1	12	memory-bound
SiLU/Sigmoid	22	8	compute-bound
Scan1D (step)	8	20	memory-bound
Conv1D (K=4)	8	8	compute-bound
Scan2D (step)	16	36	memory-bound

The scan kernels are memory-bound, confirming that the key bottleneck is state h access bandwidth, not arithmetic throughput. This motivates the CUDA Blelloch approach: by processing the entire sequence in a single kernel with shared memory, we minimize global memory traffic.

8 Backward Pass and Adjoint

The adjoint of the SSM recurrence (6)–(7) is derived as follows. Let $g_t^{d,m} = \partial\mathcal{L}/\partial h_t^{d,m}$.

Reverse-mode accumulation ($t = L-1, \ldots, 0$):

$$g_t^{d,m} = C_t^{d,m} \frac{\partial \mathcal{L}}{\partial y_t^d} + a_{t+1}^{d,m} g_{t+1}^{d,m} \tag{17}$$

with $g_L = 0$. Parameter gradients:

$$\nabla_{C_t^{d,m}} \mathcal{L} = \frac{\partial \mathcal{L}}{\partial y_t^d} \, h_t^{d,m} \tag{18}$$

$$\nabla_{B_t^{d,m}} \mathcal{L} = g_t^{d,m} \, \delta_t^d \, x_t^d \tag{19}$$

$$\nabla_{A^{d,m}} \mathcal{L} + = g_t^{d,m} \, h_{t-1}^{d,m} \, \delta_t^d \, a_t^{d,m} \tag{20}$$

$$\nabla_{x_t^d} \mathcal{L} + = \sum_m g_t^{d,m} \, \delta_t^d \, B_t^{d,m} \tag{21}$$

$$\nabla_{\delta_t^d} \mathcal{L} + = \sum_m g_t^{d,m} \big(h_{t-1}^{d,m} \, A^{d,m} \, a_t^{d,m} + B_t^{d,m} \, x_t^d \big) \tag{22}$$

Note that (17) is itself a reverse scan, amenable to a reverse-direction Blelloch scan on GPU (not yet implemented; current backward uses sequential kernel).

9 Separable Convolution

While the wavefront-unified ConvND (Section 6) provides a single-kernel dense K^N implementation, we also implement the classical *separable* convolution as a cascade of N 1D convolutions. This reduces computational complexity from $O(K^N)$ to $O(N \cdot K)$ per position.

9.1 Implementation

Each axis is processed sequentially using the same wavefront infrastructure:

```
// Cascade: N 1D convolutions with ping-pong buffers
for axis in 0..N-1:
    convnd_separable_1d_wavefront(input, output, kernel[axis], axis)
    swap(input, output)
```

The separable approach requires $N \cdot K$ multiplications per spatial position versus K^N for the dense kernel.

9.2 CPU vs GPU Performance

Surprisingly, the performance winner depends on the execution platform:

Table 6: ConvND performance: Dense K^N vs Separable cascade (2D grids, D=64, K=3).

Platform	Grid	Dense (ms)	Separable (ms)	Speedup
CPU (AVX2)	256×256	135.5	34.6	3.9×
CPU (AVX2)	512×512	927.4	204.4	4.5×
GPU (MX450)	256×256	5.30	7.13	0.74×
GPU (MX450)	512×512	15.1	19.9	0.76×

On CPU, separable wins due to reduced arithmetic (6 vs 9 multiplications). On GPU, dense wins because (1) single kernel launch avoids launch overhead, (2) better memory coalescing, and (3) the GPU masks computational complexity via massive parallelism. This motivates providing both implementations.

10 Experiments

All benchmarks were measured on: CPU: x86-64 AVX2, GCC 13.3.0, `-O3 -mavx2`; GPU: NVIDIA MX450 (sm_75), CUDA 12.0.

10.1 GEMM

AVX2 achieves 9.5× speedup over scalar C at $n = 512$ (Table 4), driven by `vfmadd231ps` pipelining. GEMM at $n = 512$ is compute-bound ($I = 85$ FLOP/Byte), explaining why AVX2 provides near-linear speedup with vector width.

10.2 Wavefront Parallelism

Table 2 confirms Theorem 1 to within 0.1% across all tested grid sizes. At $d = 64$, the 32.25× speedup enables processing a $64 \times 64 \times 32 \times 8$ SSM state in 33.6 ms versus 1084 ms sequential.

10.3 Blelloch Depth

At $L = 1024$: Blelloch requires 20 synchronization barriers versus 1024 sequential steps — a 51× depth reduction (Table 7, measured analytically).

Table 7: Blelloch depth vs sequential depth.

L	Seq. depth	Blelloch depth	Ratio	CUDA blocks
64	64	12	5.3×	DM
128	128	14	9.1×	DM
256	256	16	16×	DM
512	512	18	28×	DM
1024	1024	20	51×	DM

10.4 Optimizer Tests

MUONCLIP and AdamW (CPU and CUDA) pass all 6 tests: gradient clipping (no-op and active), MUON step, AdamW step, and CPU/CUDA consistency with max diff 2.98×10^{-8} (float32 precision).

11 Discussion

Limitations. (1) The ASM scan1d kernel does not vectorize over the state dimension M due to the sequential dependency chain in L — the scan is memory-bound. (2) Blelloch requires $L \leq 1024$ in shared memory on current hardware. (3) The expf() call in the scan kernel is not AVX2-vectorized; a polynomial approximation (≈ 8 FLOPs) would remove this bottleneck. (4) The backward scan is currently sequential; a reverse Blelloch scan would halve backward latency.

N-dimensional generalization. Equation (10) directly extends to $N > 2$ dimensions by summing over N predecessor states. For $N = 3$ (video: height × width × time), the wavefront is an anti-tetrahedron with $O(d^2)$ parallel elements per diagonal. The general speedup for a d^N hypercube is $S_N(d) = d^N / \binom{N(d-1)}{N} \approx d^{N-1}/N!$ (asymptotically).

12 Related Work

Mamba [3] is the direct predecessor. S4 [4] provides the theoretical foundation. VMamba [8] and Mamba-ND [7] are the closest multi-dimensional extensions; our main distinction is true simultaneous ND recurrence. The Blelloch scan [2] and its GPU implementation [5] are the algorithmic foundation of our CUDA kernel. MUON [6] with Newton-Schulz orthogonalization [1] is our optimizer. The roofline model [9] guides our kernel classification.

13 Conclusion

We presented K-Mamba, a native N-dimensional Mamba SSM library with five key contributions: (1) a formal proof that $d \times d$ wavefront scheduling achieves $d/2$ speedup, experimentally validated to 0.1% accuracy; (2) a reusable ND topological layer eliminating code duplication between scan and convolution operators; (3) a Blelloch parallel prefix scan reducing CUDA SSM depth from $O(L)$ to $O(\log L)$ with exact same work; (4) separable ConvND with empirical characterization showing algorithmic optimality depends on execution platform (CPU vs GPU); (5) a zero-dependency C/ASM/CUDA implementation of the full training stack including MUONCLIP optimizer, all without Python or external ML libraries.

K-Mamba demonstrates that industrial-quality SSM inference and training does not require large software stacks — a few thousand lines of C, assembly, and CUDA suffice.

A Monoid Associativity Proof

Proposition 2. *The operator* $(a_1, b_1) \otimes (a_2, b_2) = (a_1 a_2,\ a_2 b_1 + b_2)$ *is associative.*

Proof. Let $X_i = (a_i, b_i)$. $(X_1 \otimes X_2) \otimes X_3 = (a_1 a_2,\ a_2 b_1 + b_2) \otimes (a_3, b_3) = (a_1 a_2 a_3,\ a_3(a_2 b_1 + b_2) + b_3) = (a_1 a_2 a_3,\ a_2 a_3 b_1 + a_3 b_2 + b_3)$.

$X_1 \otimes (X_2 \otimes X_3) = (a_1, b_1) \otimes (a_2 a_3,\ a_3 b_2 + b_3) = (a_1 a_2 a_3,\ (a_2 a_3) b_1 + a_3 b_2 + b_3)$.

Both expressions are equal. □ □

B Wavefront Parallelism for $d_1 \neq d_2$

For a $d_1 \times d_2$ grid with $d_1 \leq d_2$:

- $d_1 + d_2 - 1$ total diagonals.
- Maximum diagonal size: $\min(d_1, d_2) = d_1$.
- Speedup: $S = d_1 d_2 / (d_1 + d_2 - 1)$.

For $d_1 = d_2 = d$: $S = d^2/(2d - 1) \approx d/2$, matching Theorem 1.
